APPENDIX II: Final Stage of the Charge Transfer Process in Charge Coupled Devices

Published on IEEE TRANSACTIONS ON ELECTRON DEVICES, VOL. ED-21, NO. 4 APRIL 1974
Final Stage of the Charge-Transfer Process in Charge-Coupled Devices

YOSHIKAI DAIMON, AMR M. MOHSEN, AND T. C. McGILL, MEMBER, IEEE

Abstract—The final stages of transfer of charge from under a storage gate is formulated analytically including both fringing-field induced drift and diffusion. Analytic solutions to these equations are presented for constant fringing fields, and a system of equations for spatially varying fields is developed. Approximate solutions for spatially varying fringing fields, when combined with a lumped-parameter model of the self-induced field effects, are shown to give a reasonably accurate representation of the free-charge transfer process.

I. INTRODUCTION

EARLY descriptions [1], [2] of the charge transfer in charge-coupled devices (CCD) assumed that during the final stage of the charge transfer, the mechanism of transfer would be diffusion from under the storage gate. However, subsequent studies of the surface-potential profiles under the gates [3] indicated that fringing-field induced drift could act as an additional charge-transfer mechanism. In certain designs of CCD, this second mechanism can actually act as the dominant mechanism for transfer and enhance the rate of transfer during the final stage of charge transfer [4], [5].

These two mechanisms of transfer are characterized by two time constants, the thermal-diffusion time constant, \( r_d \), and the single-carrier transit time constant, \( r_s \). In the case when the fringing fields are zero, the final stages of the diffusion process are characterized by a profile which is a cosine function in shape and which decays exponentially with a time constant given by

\[
\tau_d = \frac{4L^2}{\pi^2 D}
\]

(1)

where \( L \) is the length of the storage electrode, and \( D \) is the diffusion constant.

On the other hand, if we neglect diffusion phenomena, the charge remaining under the storage gate will be swept out in a single-carrier transit time

\[
\tau_s = \int_0^t \frac{dz}{\mu E(z)}
\]

(2)

In this paper, we study these results analytically. We show that it is possible to obtain an analytic solution of the continuity equation in which the combined effects of diffusion and a uniform fringing field are included. A set of equations for spatially varying fringing fields are developed to show that the analytic solution for spatially varying fringing fields can also be written in a form analogous to that for constant fringing fields.

The standard variational method is applied to obtain an approximate analytic expression for the characteristic time constants for spatially varying fringing fields. Self-induced drift terms are included by using an approximate lumped-circuit model.

II. TRANSPORT DYNAMICS

The transport dynamics along the insulator-semiconductor interface are described by the continuity equation

\[
\frac{\partial q}{\partial t} + \frac{\partial}{\partial x} J_x = 0
\]

(3a)

and the diffusion equation

\[
J_x = -D \frac{\partial q}{\partial x} + \mu q \left( \frac{\partial\phi}{\partial x} \right)
\]

(3b)

where \( q \) is the surface-charge density, \( \phi \) is the surface potential, and \( x \) is the distance along the interface in the direction of charge transfer. \( J_x \) is the sheet-current density.

In this paper, we want to consider the solution to (3) for boundary conditions and approximations appropriate to the case where the storage gate contains a small amount of charge. This condition will arise in the final stage of the charge transfer, in the complete charge-transfer mode [5], or when the CCD is operated in a low-level injection application, such as low light-level imaging. In these cases, we can neglect the first approximation neglect the self-induced field terms.

When a CCD is operated in the complete charge-transfer mode, detailed numerical simulation of the transport dynamics under all the relevant gate electrodes and interelectrodes regions show that the charge transfer in the last stages of the charge transfer process can be approximately described by the discharge of the storage gate with an almost perfect sink at one end [5]. Therefore, we have considered the solution of (3) for the discharge of the storage gate using the boundary conditions

\[
q(t, L) = 0, \quad \text{for } t > 0
\]

(4a)

\[
J_x(t, 0) = 0, \quad \text{for } t > 0
\]

(4b)

Condition (4a) corresponds to assuming a perfect sink at
the right-hand end of the storage gate \( z = L \); (4b) corresponds to assuming that no current flows out of the bucket under the storage gate through the edge at \( z = 0 \).

III. CONSTANT FRINGING FIELD

Assuming a constant fringing field \( E \) under the storage gate and neglecting the self-induced field term, the residual surface-charge profile under the storage gate is given by solving (3) to obtain

\[
q(t,x) = \frac{x}{L} \cdot \frac{Ez}{2kT} \exp \left( \frac{\frac{x}{2} \cdot C_s \left( 1 - \frac{x}{L} \right) \exp \left( -\frac{t}{\tau_s} \right) \right)
\]

where \( kT \) is the thermal voltage and \( n \) is a summing index.

The solution is given by a Fourier expansion multiplied by a common function, \( \exp \left( \frac{Ez}{2kT} \right) \), with constants \( C_s \), \( \tau_s \), and \( A_s \) to be determined as follows.

\( C_s \) is determined by the boundary condition at \( z = 0 \) and is given by solving the transcendental equation (see Fig. 1)

\[
\tan \left( \frac{x}{2} \cdot C_s \right) = \frac{\frac{Ez}{2kT} \cdot C_s}{Ez} = 0
\]

where \( C_s \) is in the range given by

\[
2n - 1 \leq C_s < 2n, \quad \text{for } n = 1, 2, \ldots
\]

(6b)

\( \tau_s \) given by substituting (3) into (3) to obtain

\[
1 = C_s^{\frac{2}{n}} \cdot 4D + (\frac{nE}{4})^4 D
\]

(7)

Noting that the exponential term, \( \exp \left( \frac{Ez}{2kT} \right) \) in (5) can be taken outside of the summation, we then obtain

\[
A_s = \frac{2}{L} \left[ 1 - \sin \left( \frac{1}{2} \cdot C_s \right) \right] \int_0^{\frac{x}{2}} \exp \left( -\frac{Ez}{2kT} \right) \sin \left( \frac{x}{2} \cdot C_s \left( 1 - \frac{x}{L} \right) \right) dx
\]

where use of the boundary condition (6a) has been made.

Detailed numerical simulations [4], [5] of charge transfer, including the effects of fringing fields, show that the profile of charge changes for a single-carrier transit time and then becomes stationary with an exponential time decay of the amplitude. This result is easily understood in light of the solution presented in the previous discussion. From (7) and (6b), one can see that \( \tau_s \) is a decreasing function of \( n \). Hence, for reasonably smooth initial charge distributions which produce finite values of \( A_s \), which either remain relatively constant or decrease with increasing \( n \), we expect that essentially the first term in the series in (3) dominates the series, and \( q(t,x) \) can be approximated by

\[
q(t,x) \approx A_s \exp \left( \frac{Ez}{2kT} \right) \sin \left( \frac{x}{2} \cdot C_s \left( 1 - \frac{x}{L} \right) \right) \exp \left( -\frac{t}{\tau_s} \right)
\]

where we have replaced \( \tau_s \) by \( \tau_r \) to indicate that it is the time constant characterizing the final decay of the charge. Using (7), we find that

\[
\frac{1}{\tau_r} = C_s^{\frac{2}{n}} \cdot 4D + (\frac{nE}{4})^4 D
\]

(10)

Hence, we find for times which are greater than some as yet to be determined time (see Section IV), the charge profile remains constant, and the amplitude decays exponentially with time. The charge profiles at several different times are shown in Figs. 2 and 3 to illustrate the details of the charge transfer.

Determination of the value of \( \tau_r \) depends upon the value of \( C_s \). The results of a numerical solution of (6a) for \( C_s \) as a function of the dimensionless parameter \( EL/kT \), are plotted in Fig. 4. From this plot, we see that \( C_s \) ranges from 1 for \( EL/kT = 0 \) to a value of 2 as \( EL/kT \) approaches infinity. (Note the first term in (6a) is negative.)

To compare this final decay constant with the 2 characteristic times defined in Section I, we have computed the value of the ratio \( \tau_r / \tau_a \) to be

\[
\frac{\tau_r}{\tau_a} = \frac{C_s^{\frac{2}{n}} + (\frac{4nE}{4})^4 D}{\tau_a}
\]

(11a)

and the value of the ratio \( \tau_r / \tau_a \) to be

\[
\frac{\tau_r}{\tau_a} = \frac{C_s^{\frac{2}{n}} + (\frac{4nE}{4})^4 D}{\tau_a}
\]

(11b)

These ratios as a function of \( EL/kT \) are plotted in Fig. 5.

IV. STATIONARY PROFILE WITH CONSTANT FRINGING FIELD

According to the detailed numerical simulation [1], [5] of charge transfer under the influence of fringing fields, the charge profile under the storage gate drifts for a
carrier transit time, this ratio can be written as
\[ r_{ab} = \exp \left( \frac{t \cdot e^{2}kT}{4E/L} \frac{C_g - C_0}{C_g} \right). \]

Taking as our criterion the fact that the value of the exponent in this expression is greater than one, we find that (9) is valid for
\[ t > \frac{4E/L \cdot e^{2}kT}{C_g - C_0}. \]  

(12)

The right-hand side of this inequality is a multiple of the \( r_{ab} \), with the constant multiplying the transit time depending on the value of the parameter \( E/L \cdot kT \). The value of this multiplier can be approximated as follows.

The value of \( C_g - C_0 \) varies monotonically between 8 when \( E/L \cdot kT \) is 0 to 12 when \( E/L \cdot kT \) approaches infinity. Thus we can replace the inequality by
\[ t > \frac{E/L \cdot kT}{2e^2}. \]  

(13)

This inequality shows that for \( E/L \cdot kT \) between 0 and about 30 (the values normally encountered in devices), the approximation is valid for times greater than a single-carrier transit time. Hence, the results of the numerical simulations are in good agreement with the analytical results obtained here, and we can describe the final charge profile by (9).

The peak position of the charge packet, \( x_{\text{peak}} \), after it becomes stationary under the storage gate, is given by differentiating (9) with respect to \( x \) and setting the resulting equation to be 0. Then using the condition (6a), we obtain
\[ x_{\text{peak}} = 2L \left( 1 - \frac{1}{C_0} \right). \]  

(14)

This expression shows the peak-position varies with the strength of the fringing field. For 0 field, \( C_0 \) is unity. The surface-charge profile is a cosine function with a maximum at \( x = 0 \), and it decays exponentially with the time constant equal to the thermal-diffusion time constant.

For large fringing fields, the value of \( C_0 \) approaches 2 as shown in Fig. 4, but never becomes larger than 2. For extremely large fringing fields, \( C_0 \) \( \approx \) 2 and \( x_{\text{peak}} \approx L \), implying that the peak position approaches the sink edge at \( x = L \). At times, the exponential decay is observed satisfying the inequality in (12), and the characteristic decay time is a factor approximately \( 1 \) of the single-carrier transit time, as we observe in Fig. 5. Figs. 2 and 3 illustrate the details of the charge decay as we have discussed so far.

V. SPATIALLY VARYING FRINGING FIELDS

We now note that the constant and spatially varying fringing fields both give similar charge-decay characteristics. This is to say that the analytic solutions of both spatially varying and constant fringing fields can be written in similar forms. Both solutions can be expressed by infinite series, and as time elapses, the term with the
Fig. 3. The details of the charge decay at different stages. The condition is similar to the results of Fig. 2 except the fringing field is spatially varying in this case. An average fringing field computed by (2) is 140 V/cm. The minimum field is 24 V/cm. The total number of profiles shown is 16. The corresponding times are the same as Fig. 2(b) and (c).

Fig. 4. Values of $C_i$ defined by (6), plotted against the normalized fringing-field strength $EL/2T$.

Fig. 5. The final decay time constant $\tau_f$, normalized by the single-carrier transit time $\tau_t$ and by the thermal-diffusion time constant $\tau_\alpha$, plotted against the normalized fringing-field strength $EL/2T$.

The charge profile $Q(t,x)$ is then given by

$$Q(t,x) = \int_0^t q(t,x') \, dx'.$$

The largest time constant $\tau_f$ becomes dominant, resulting in the exponential decay characteristics and the constant charge profile. In this case, it is convenient to work with
Using the definition for $Q$ and the fact that current flows only out of one end of the gate (see (4b)), we can write (3) as

$$ \frac{dQ}{dt} = D \frac{\partial Q}{\partial x} - \mu E(x) \frac{dQ}{dx} $$

(16)

where again, we have replaced $\tau_i$ by $\tau_f$.

The largest time constant $\tau_f$ could, in general, be obtained by solving (19) and (20). However, a good estimate can be obtained from the standard variational procedure for lowest eigenvalues [3]. According to this procedure, the exact value of $\tau_f$ is obtained by minimizing

$$ \frac{1}{\tau_f} = \left[ D \int_0^L \left( \frac{dE(x)}{dx} \right)^2 + \left( \frac{dx}{dE(x)} \right)^2 \right] \int_0^L \gamma_f^2(x) \, dx $$

(23)

The solution of (19) with $E(x)$ constant suggests the trial function for the first eigenfunction

$$ \gamma_1(x) = \sin \left( \frac{x C_1}{2L} \right) $$

(24)

This trial function must satisfy the boundary conditions of (20). That is, the value of $C_1$ is to be determined by the strength of the fringing field $E(L)$ at the sink edge of the gate (see 20a)). Since the fringing fields at the ends of storage gates are very large [3], [5], we have

$$ E(L) >> kT/L $$

(25)

Hence, substituting $\gamma_1(x)$ of (24) into $R$ of (20a), we obtain

$$ -\tan \left( \frac{C_1}{2} \right) = \frac{kT}{2L E(L)} \ll 1 $$

(26a)

and hence,

$$ C_1 \approx 2 $$

(26b)

With this value of $C_1$, substituting the trial function given by (24) into (22), we obtain

$$ \frac{1}{\tau_f} = \frac{4}{\tau_{in}} + \frac{\mu E_{in}^2}{4D} $$

(27a)

$E_{in}$ is an equivalent constant fringing field for the spatially varying fringing field $E(x)$ and is given by

$$ E_{in}^2 = \frac{2}{L} \int_0^L \left( E'(x) - 2kT \frac{dE}{dx} \right)^2 \sin \frac{\pi x}{L} \, dx $$

(27b)

Note that, due to the weighting function $\sin^2 (nx/L)$, the integral vanishes at both ends of the gate, $x = 0$ and $L$. The contribution of the integral at the ends of the storage gate is relatively small, but the fringing fields at the positions of high-charge concentration are weighted heavily in the integral. If the fringing field is slowly varying and is at its minimum value $E_{min}$ under most of the storage gate (except at the ends), then we obtain $E(x) \approx E_{min}$ and $dE/dX \approx 0$. Hence, from (27b), we have

$$ E_{in} \approx E_{min} $$

Finally, we obtain an approximate analytic formula of the time constant for spatially varying fringing fields, which is

$$ \frac{1}{\tau_f} = \frac{4}{\tau_{in}} + \frac{\mu E_{min}^2}{4D} $$

(28)

Care must be taken in applying this formula. This formula
was obtained for slowly varying fringing fields under most of the storage gate, and other configurations may give different fringing-field profiles leading to different results.

For example, in CCD structures with short storage-gate length \( L \), \( E_{\text{sn}} \) may be a few times larger than \( E_{\text{ss}} \). In this case, \((27b)\) could be used to obtain \( E_{\text{sn}} \) if the fringing-field profile is known. For short storage-gate length \( L \), the spatial dependence of the fringing fields can be approximated by \((25)\):

\[
E(x) = \begin{cases} 
\frac{E_{\text{sn}}L}{2x}, & 0 \leq x \leq L/2 \\
\frac{E_{\text{sn}}L}{2(L-x)}, & L/2 < x \leq L
\end{cases}
\]

Substituting \((29)\) into \((27b)\), we obtain \( E_{\text{sn}} = 1.5E_{\text{sn}} \) for the same trial function \( q(x) \) given by \((24)\). In either case, as seen in \((28)\), we note that the reduction of the final decay time constant by the fringing-field strength is quadratic rather than linear.

If we include the nonlinear self-induced field drift, exact analytic solutions of \((3)\) become difficult. However, using a lumped-circuit model, the charge-transfer characteristics can be obtained by solving the discharge equation \([7],[6]\):

\[
J_x = -\frac{dQ(t,L)}{dt}
\]

where \( J_x \) is the steady-state discharge current density assumed constant across the gate, and \( Q(t,L) \) is the total charge under the gate.

The relation between the surface potential \( \phi_s \) and surface-charge density \( \rho \), under the transfer gate, is given according to the gradual channel approximation \([4],[5]\):

\[
\phi_s = \phi_{\text{ss}} + \frac{\rho}{C}
\]

where \( \phi_{\text{ss}} \) is the surface potential with no charge, and \( C \) is the effective oxide- and depletion-layer capacitance per unit area. When the fringing fields are negligible compared to the self-induced field, we have

\[
\frac{\partial \rho}{\partial x} \approx \frac{1}{g} \frac{\partial \phi_s}{\partial x}
\]

Then, if the difference in the surface potential between the beginning and end of the gate is \( \Gamma \), by integrating the diffusion equation \((3b)\) over space, we obtain \([5],[7]\):

\[
J_x = \frac{\mu C}{2L} \left[ 1 - e^{-2kTV} \right]
\]

where, we note

\[
Q(0) = CV
\]

Since \( J_x \) in \((3b)\) is assumed constant for \( 0 \leq x \leq L \), we

\[\text{Chapter Two}\]

\[\text{Fig. 6. The surface potential and electric field along the Si-SiO\textsubscript{2} interface obtained from the solution of the two-dimensional Poisson's equation. The electrode voltages correspond to the lower stages of the charge transfer with a signal charge in the receiving storage gate. The substrate doping is } 10^{19} \text{ cm}^{-2}. \text{ The fixed surface-state charge is } 3.0 \times 10^{10} \text{ cm}^{-2}. \text{ In this calculation,}\]

obtain \( q(x) \) for \( 0 \leq x \leq L \). Then, by integrating \( q(x) \), we obtain

\[
Q(t,L) = \frac{1}{2} CV \left[ V + 2kTV \right]
\]

Then, the solution of \((30b)\) is of the form

\[
Q(0,L) = Q(0,L) \exp \left( -t/\tau \right)
\]

where \( Q(0,L) \) is the initial total charge under the storage gate, and \( \tau \) is given by \((28)\).

\[\text{VI. NUMERICAL RESULTS}\]

The exact fringing-field profile can be obtained by solving the two-dimensional Poisson equation for the CCD structure with the applied gate voltages. In Fig. 6, we have plotted the surface potential and surface-potential gradient along the semiconductor-insulator interface. The voltages on the gate electrodes (see Fig. 6) are those corresponding to the last stage of the charge transfer. Most of the signal charge was taken to be in the receiving storage electrode.\(^1\) Periodic boundary conditions were used. The minimum fringing field \( E_{\text{sn}} \), in this case, is equal to 74 V/cm.\(^2\)

To check the accuracy of the approximate solution for \( \tau \) given by \((28)\), we have solved \((3)\) numerically for the fringing-field profile given in Fig. 6 \([2]\). The full-line curve in Fig. 7 represents the numerically calculated residual charge under the storage gate versus transfer time with the self-induced fields. The dashed-line curve in Fig. 7 is the residual charge calculated using \((32)\). The value

\[\text{\textsuperscript{1}For two-phase push-clock scheme, the actual receiving gate voltage is } -8.5 \text{ V instead of } -9.8 \text{ V in Fig. 3, and the difference of } 3.3 \text{ V corresponds to the amount of the signal charge present under the receiving gate.}\]
Chapter Two

of the final decay time constant \( \tau_f \) calculated from (28) is 22.7 ns compared to 21.2 ns obtained from the numerical solution.

VIII. CONCLUSION

Incomplete transfer of free charge in CCD with small amounts of charge to be transferred was characterized analytically, including the effects of diffusion and fringing fields. We have found that, independent of the fringing-field profile, the exponential decay characteristic is solely due to diffusion. However, the characteristic time constant \( \tau_f \) for the decay depends on diffusion and fringing fields and is found to be always a fraction of the single-carrier transit time \( \tau_T \) (see Fig. 5).

The standard variational procedure was applied to obtain an approximate analytic expression for the characteristic time constant (see (23)), and the expression was evaluated for spatially varying fringing fields (see (26)) which vary relatively slowly over most of the storage gate length but increase considerably at the edges of the gates. Such fringing-field profiles are typical for most minimum geometry CCD structures (minimum gate dimension of about 10 \( \mu \) and substrate doping greater than 10^{15} cm^{-3}).

The constant and spatially varying fringing fields both were found to give exponential charge-decay characteristics. When the magnitude of the field becomes greater than a few times \( \kappa T/L \), the discharge is considerably enhanced by the fringing-field drift.

If the self-induced field terms are introduced, then, using a lumped-circuit model, the free-charge transfer process is given quite accurately by the formula given.
